Abstract

We look into the issue that the amount of entropy kept by the pseudorandom number generator (PRNG) of Android is constantly low. We find that the accusation against this issue of causing poor performance and low frame rate experienced by users is ungrounded. We also investigate possible security vulnerabilities resulting from this issue. We find that this issue does not affect the quality of random numbers that are generated by the PRNG and used in Android applications because recent Android devices do not lack entropy sources. However, we identify a vulnerability in which the stack canary for all future Android applications is generated earlier than the PRNG is properly setup. This vulnerability makes stack overflow simpler and threats Android applications linked with native code (through NDK) as well as Dalvik VM instances. An attacker could nullify the stack protecting mechanism, given the knowledge of the time of boot or a malicious app running on the victim device. This vulnerability also affects the address space layout randomization (ASLR) mechanism on Android, and can turn it from a weak protection to void. We discuss in this paper several possible attacks against this vulnerability as well as ways of defending. As this vulnerability is rooted in an essential Android design choice since the very first version, it is difficult to fix.

I. INTRODUCTION

A. Motivation

Our motivation roots in an issue reported to the Android Open Source Program [1], which complained about the constantly low amount of entropy kept by the PRNG affected the overall performance and user experience, causing low frame rate in the UI layer. There was a solution protecting the overall performance and user experience, causing constantly low. We find that the accusation against this issue of causing poor performance and low frame rate experienced by users is ungrounded. We also investigate possible security vulnerabilities resulting from this issue. We find that this issue does not affect the quality of random numbers that are generated by the PRNG and used in Android applications because recent Android devices do not lack entropy sources. However, we identify a vulnerability in which the stack canary for all future Android applications is generated earlier than the PRNG is properly setup. This vulnerability makes stack overflow simpler and threats Android applications linked with native code (through NDK) as well as Dalvik VM instances. An attacker could nullify the stack protecting mechanism, given the knowledge of the time of boot or a malicious app running on the victim device. This vulnerability also affects the address space layout randomization (ASLR) mechanism on Android, and can turn it from a weak protection to void. We discuss in this paper several possible attacks against this vulnerability as well as ways of defending. As this vulnerability is rooted in an essential Android design choice since the very first version, it is difficult to fix.

B. Linux PRNG and Our Assumption

Android runs on a Linux kernel. The /dev/random and /dev/urandom devices are backed by the Linux PRNG. Figure 1 shows its general structure [5]. In this section, we briefly describe how it works and its properties related to our work.

The Linux PRNG consists of three entropy pools which act in a same manner. They have two major functions: mix entropy into the pool and extract entropy from the pool. The input pool (also known as the primary pool) gets entropy from three types of entropy sources: disk, interrupt and input events. When an event happens in a source, the source feeds the timing and the type of the event to the input pool. The two output pools (secondary pools) get their entropy by extracting entropy from the input pool. The blocking pool blocks upon no entropy in both its pool and the input pool while the non-blocking pool does not. An important property of the non-blocking pool is that it does not extract any entropy if the amount of entropy in the input pool is less than 192 (random_read_wakeu_p_thresh * 3 / 8) bits. When there is no entropy mixed into the non-blocking pool, its output is deterministic and predictable given any of its internal states between the last entropy mix and the number of extractions from it.

The three pools are initialized when the kernel initializes the random character device. On initialization, the pools are not wiped and the time and machine information are mixed in. Under traditional Linux environment, there is an init script which reads the saved random seed from the disk and mixes it into the nonblocking pool.

Our assumption on Linux PRNG is the following: after the first time when /dev/urandom extracts enough entropy (for example, the minimum amount of extraction, 60 bits) from the input pool, /dev/urandom is secure. It makes no difference that the amount of entropy is low or high after this time point.

The rest of the paper is organized as follows. In section 2, we introduce existing work on analyzing Linux PRNG and the low entropy issue, as well as the work aiming at exploiting or defending buffer overflow. Section 3 describes our investigation methodology. Section 4 shows the result of
our investigation, revealing several vulnerabilities. In Section 5 we discuss the effect of these vulnerabilities and possible attacks and defenses. Finally, in section 6 we draw our conclusion.

II. RELATED WORK

Previous work was done to analysis the security of the Linux PRNG, especially the non-blocking pool, from a cryptographic point of view [5]. It showed that given the internal state not known to the attacker, predicting the output of the non-blocking pool is as hard as reversing the SHA-1 hash function, even if there is not any entropy mixed in. We base our work on this assumption and do not want to challenge it.

There was also work focusing on what could happen before /dev/urandom being properly seeded and its internal state being completely unpredictable and unknown to the attacker. [6] successfully caught such a vulnerability that on some embedded devices the ssh-keygen was invoked before /dev/urandom was ready, resulting in identical or factorable RSA private keys. Our goal is to find if a similar vulnerability exists on Android devices which are more complicated and not investigated. And our result and conclusion turn out to be different from that for embedded devices: we find that the user applications do not suffer from the low entropy issue while it is the buffer overflow protecting mechanisms, implemented in the kernel and other parts of Android framework that suffer from it.

Stack canary [4] is an protecting mechanism that can detect buffer overflow on the stack and terminate the program before attacker taking control of it. It works by putting several bytes in the stack frame, right before the return address and checking if the contents are changed before the function returns. Two major types of canaries are proposed: 1) terminator canary: it contains terminator characters on which the string operations stops and 2) random canary. Android platform has random canary implemented since version 4.0. As shown in section 4, we identified a vulnerability that the attacker could know the canary value of all Android apps by installing a malicious app or simply guess the canary with the cost not depending on the length of the canary.
attacker still cannot predict its output, while the security of 
/dev/urandom device depends on whether there is enough
entropy mixed in, and whether its internal state is not known
to the attacker. Hence we focus only on /dev/urandom.

We want to know:

1) Whether /dev/urandom is ever properly seeded:
never being properly seeded could result from the
amount of entropy never crossing the threshold of 192
bits due to lack of entropy sources combined with the
random seed not being properly saved and restored, or
in the first boot.

2) If /dev/urandom is eventually properly seeded, then
does the entropy accumulates rapidly enough so that
when any application that requires high quality random
numbers is invoked, /dev/urandom is ready.

To answer the above questions, we did the following:

1) Instrumented the kernel to capture every event that
contributes entropy to the input pool as well as the
amount of entropy before and after that event. We also
captured the events that extract entropy from the input
pool and the amount of entropy before and after them.
The time of above events, as well as the time when the
user can operate the device are recorded. With the above
result, we collected the typical amount of contribution
of the three event types.

2) With the result of 1), we investigated what processes
read from /dev/urandom before its pool getting the
first entropy mix.

3) After we found that virtually every process read from
/dev/urandom in order to set up its stack canary,
we manually read the related Linux Kernel and Android
source to to figure out how and when the canaries are
set. We also investigate the ASLR implementation on
arm architecture by source code reading.

4) After we identified the predictable canary value issue,
and found that given the same initial state, there could
be different canary values due to different scheduling
realizations, we did experiment to see how much entropy
does the scheduling bring.

IV. RESULTS AND INTERPRETATION

A. Performance

We searched in the source code of Android framework
since version 4.0 for string "\dev/random" and found
no reference to it. We also captured all read operation on
/dev/random in a daily used of a Nexus 7 tablet since
boot, and found only once: process wpa_supplicant read
from it. It is a WPA authentication helper and it uses
/dev/random to initialize its own PRNG on start.

All Android applications who want high quality ran-
dom numbers are recommended to use a Java class
named SecureRandom, which on construction read from
/dev/urandom to seed its internal generator.

These results indicate that the performance issue cannot be
attributed to blocking read of /dev/random since there are
almost none.

**TABLE II: Full Boot Time:** The time it takes from when
the kernel is loaded to when the Android desktop launcher is
brought up.

There may be some links between the entropy collecting
diode and the poor performance. We noticed that since Linux
kernel 3.7, the code of the input event entropy source handler
in input subsystem has been restructured to improve the perform-
ance on multitouch devices by batching the input events [3].
Some developers commenting on Issue 42265 also suggested
that the performance issue is due to suboptimal order of event
processing and entropy accumulation. We cannot tell if there
would be any improvement since we did not successfully
install a kernel later than 3.7 on our devices, but we do suggest
users keep their software up-to-date since the changes are quite
reasonable and promising.

B. Security

1) Entropy Sources: Figure 2 suggests that the And-
roid devices have sufficient sources of entropy. The en-
tropy contributed merely by disk events is enough to have
/dev/urandom properly seeded before any user applications
can run.

2) User Applications: Figure 2 and table II show that the
time when the user could start the first application is after
the time when the amount of entropy first crossed the 192
threshold, which means the first read from /dev/urandom
will cause the non-blocking pool to extract at least 10 bytes
(EXTRACT_SIZE defined in random.c). The 80 bits en-
tropy is enough to prevent any attacker trying to predict the
random number. There will be more entropy mixed in when
user touches or slides on the screen as shown in table 3. If
it is the first boot, users will be asked to setup the wireless
network and enter Google account information, which cause
a lot of input events and further secure the /dev/urandom
device.

Therefore we conclude that the user applications are able to
enjoy high quality random numbers from the beginning.

3) Saving and Restoring the Random Seed: Android frame-
work has a system service named EntropyMixer which re-
places the traditional init script to restore the random seed at
boot. There are two major differences between them that may
cause security issues:

- EntropyMixer is an Android service which starts after
the Android framework is initialized. Any processes
starting before are not protected by the saved entropy.
/dev/urandom is merely seeded by the time of boot
and the machine information before that.

- EntropyMixer reads /dev/urandom to save the random
seed on boot and then saves every 3 hours instead of
before rebooting or halting. This may be a better choice
since cell phones are not likely to reboot or halt normally, but it also means the amount of entropy of the saved seed is less than or equal to the amount of entropy of the time of first boot, if the device is rebooted within three hours of its first boot.

4) Shared Stack Canary: We found that virtually all processes need to read from /dev/urandom at their start. We looked into why and found that recent Android versions since 4.0 adopted the stack protector mechanism, as known as stack canaries to protect the native Android framework processes as well as native code bridged by Java Native Interface in user applications.

The stack protector works with the help of two components:
- Android NDK compiler (gcc): insert canary putting and checking code in function prologues and epilogues. The canary value is read from a global variable.
- The standard C library (bionic): initialize the canary value by reading 4 bytes from /dev/urandom and put it in a global variable. The initialization routine is a library constructor which is invoked by the dynamic linker after the library is mapped into the process’ memory space, typically when the process is exec()ed.

However, the way in which the canary value is initialized could be problematic on Android platform. All system services and user applications running on the Dalvik VM are forked from a process called Zygote [7] (Fig 3). By leveraging the Copy-on-Write fork on Linux, Android apps do not need to load the Dalvik VM executable image or the shared library repeatedly on start, leading to better performance. But it also means that there is no chance for an app to invoke the library constructor which sets the canary value. Therefore all Android processes share one stack canary.

We made an app [9] to show its canary value on the screen and compared this value to what app_process (which then forked Zygote) read from /dev/urandom on its start. The result verified this vulnerability.

5) Predictable Stack Canary: Combining section 4.2.3 and 4.2.4, we found that it is possible to predict the canary value shared by all Android apps and Zygote. Note that EntropyMixer is also a system service running on Dalvik VM
and thus is going to be forked from Zygote. Furthermore, figure 2 indicates that when Zygote starts no entropy is mixed into /dev/urandom. Therefore, when Zygote sets up its canary value, the /dev/urandom is only initialized by the kernel with the system information and the boot time.

However in our experiment, we found the canary value was not a constant when the initial state of /dev/urandom pool was fixed.

We conjectured that it was due to multitasking and different scheduling realizations, because /dev/urandom adopts a fine grained locking scheme that maximizes parallelism. It is possible that the internal state changes during the time when the current reading process is descheduled. To verify our conjecture, we modified the /dev/urandom interface to enforce a coarse grained locking scheme so that other processes cannot change the internal state before the current process finishing reading. It then showed a fixed canary value that depended only on the initial state of /dev/urandom.

Given no entropy mixed into the pool of /dev/urandom, the internal state depends only on the number of extractions from the pool (this is different from the number of bytes read from /dev/urandom, because the minimum number of bytes to extract is 10). With the non-determinism of scheduling, we can model the canary value as a function $f(B, N)$ where $B$ is the boot time and $N$ is the number of extractions from /dev/urandom that happened before Zygote read from it.

$B$ is acquired by getnstimeofday() function which supports nanosecond resolution, but we observed only microsecond precision on our devices. $B$ may not confirm to a specific distribution and the attacker may have knowledge about it in various degrees, we can only make some simple assumptions, for example, we can assume that the attacker knows the boot time with precision of second, then the attacker has to guess the microsecond out of $10^6$ values, equivalent to 20 bits of entropy.

$N$ may confirm to some distribution because it can be seen as a value affected by a set of independent events. In order to characterize its distribution, we collected its realizations from 244 times of boot; the result is shown in figure 4.

If the attacker has prior knowledge of this distribution of the number of extractions, he could guess the ranges in a high-probability-first order, which gives an expected number of guess of 133 in our case, equivalent to about 7 bits of entropy.

With the above model, we can estimate that $B$ and $N$ together will provide 27 bits of entropy, assuming the attacker knows the boot time in second.

Although the computation needed to predict the value of canary may be comparable to simply guessing the 32-bit canary, this vulnerability nullifies the additional security brought by extending the length of the canary. Furthermore, the system time is not a secret number and can be leaked via various ways.

6) Nullified ASLR: Since 4.0, Android has turned on address space layout randomization with the support of the kernel. Despite of only 8 bits of entropy is added for each mapped region, due to the fork nature of Zygote, all Android apps share one address layout, including the same base addresses of the stack, the heap and the standard C library.

V. EFFECT AND POSSIBLE ATTACKS AND DEFENSE

The sharing values and predictable canary vulnerability affects the following:

1) All Android applications using NDK: the simplest stack overflow attacks are made possible.
2) Dalvik VM: any buffer overflow vulnerability in DVM can be exploited with only weak defense mechanism.
3) Zygote: similar to 2), but Zygote runs as root and thus is more profitable to exploit.

A. Possible Attacks

Possible Attack 1 (side channel / canary collector): As all applications are sharing the stack canary and the base addresses and these values do not change until the next boot, a malicious application could read these values and use them to build payload to overflow other apps running on the device. We made an example of such an attack [9]. The malicious application could also collect these values and send to a server. If any buffer overflow vulnerability is found on a popular application, the attacker could compromise many devices as there is no stack protecting mechanism.

Possible Attack 2: guessing canary: Depending on the resolution of the hardware timer and the knowledge the attacker has, guessing the input of function $f(B, N)$ may take less time than simply guessing the canary value.

Possible Attack 3: heap overflow: Heap overflow vulnerabilities are more dangerous because it can circumvent overwriting the canary. A possible heap overflow attack only need to guess 16 bits, including the base addresses of the stack and the heap.

B. Defense

It is relatively easy to address the predictable canary issue by having Zygote write a new value into the global variable holding the canary after forking a new instance of Dalvik VM. This may bring an overhead of one page of memory due to modification on a CoW page.

The weak ASLR protection is rather hard to fix because:
- The shared base addresses is due to fork implementation.
- The Android developers choose to only `fork` instead of `exec` after `fork` to avoid repeatedly mapping same files in to the new process’ address space, for all Android apps runs on Dalvik VM and thus need a same set of shared libraries. There seems to be no better way to achieve different address layouts for each forked applications without sacrificing the performance.
- The weak protection provided by ASLR is due to the 32-bit architecture. It is hard to provide enough entropy that is preventive for attackers to guess with brute force without great modification to the Linux kernel.

VI. Future Work

More work could be done to further reduce the cost of predicting the boot time and the canary value:
- Model the scheduling before Zygote starting as a stochastic process may yield a better way to order the guessing sequence and eliminate impossible values.
- Investigate if it is possible to acquire precise time of boot. `uptime` could be a good start, but it only provides boot time in second.

Also, work should be done to analyze Android application using NDK of buffer overflow vulnerability. Most applications use NDK in their CPU intensive routines, resulting in a relatively narrow attack surface, however, these routines have to exchange data with the Java code, which is most possible for buffer overflow.

VII. Conclusion

We have investigated the low entropy issue on Android and shown that the poor performance is not caused by blocking reads to `/dev/random`, since there are almost none of them. Starting from this issue, we also have investigated possible security vulnerabilities and we have shown that the PRNGs on Android devices provide secure pseudorandom numbers for all user applications that requires them, because the entropy generated during boot is enough to seed the PRNG properly. However we have found that the stack protecting mechanism initializes the canary value shared by all future Android applications with a value read from the PRNG at an early time when the PRNG is not ready. We have shown that this vulnerability could result in less computation for guessing the canary value, depending on the knowledge of the attacker on the boot time. Furthermore, we have also shown that the shared values vulnerability could leak not only the canary value but the base addresses information, effectively nullifying the address space layout randomization mechanism on Android. We have discussed possible attacks against this vulnerability and implemented one of them. In the end, we have proposed a fix to the shared canary vulnerability and argued that the general shared values vulnerability is difficult to fix.
